Figure 1: (i) The C/DC task condition used in Experiment 1, where the crossing areas of targets face each other. (ii) The C/AC task condition used in Experiment 2, where the target crossing areas are horizontally aligned. In both tasks, the cursor was shown as a black cross at the same position as the stylus tip. The cursor trajectory was shown as a blue line.

ABSTRACT

In pointing, throughput TP is used as a performance metric for the input device and operator. Based on the calculation of *effective parameters* (width W_e and amplitude A_e), TP should be independent of the speed-accuracy tradeoff. To examine the validity of TP and effective parameters for crossing actions, we conducted two experiments using two established crossing tasks. Our results demonstrate that applying effective parameters to Fitts' law model improves the fit to the data for mixed biases in both tasks. Besides, we observed that effective parameters smoothed TP s across biases. However, unlike pointing, TP was observed to be unstable across ID s in one task, while was stable across ID s in the other task. Analyzing speed profiles showed that this was likely due to the fact that one of the tasks could be completed with a ballistic movement at low ID s, whereas this was impossible for the other task.

1 INTRODUCTION

Pointing tasks are frequently used to measure the performance of input devices and user groups when operating GUIs. However, in GUIs, there also exist trajectory-based tasks, in which users draw strokes. Crossing is a typical example of such tasks (Fig. 1), and many novel interaction techniques have been proposed for it [4, 10, 11, 15].

The movement time MT for crossing can be predicted by the same Fitts' law model as for pointing [1]. In pointing, Throughput TP is used as a measurement of performance for input devices and user groups. Theoretically, TP should be unaffected by Fitts' law's Index of Difficulty ID [17]. However, operating with different speed or accuracy biases ($Bias$), the TP calculated with the nominal ID , or ID_n , using the nominal target width W and amplitude A between targets has been shown to be different for each $Bias$ [20]. To resolve this issue, prior work recommended to smooth the difference of the $Bias$ by using the ID_e , which is calculated with the effective width W_e and effective amplitude A_e [18]. This enables a fair comparison of performance even when a user group interacts through various devices with different speed-accuracy balances. However, although Fitts' law predicts the MT of crossing, the effect of using effective parameters on crossing tasks has not been empirically verified.

To examine the applicability of throughput and effective parameters for crossing, we conducted experiments with two types of crossing tasks under three speed-accuracy biases. If effective parameters can appropriately normalize the speed-accuracy bias, the

model fit when analyzing all biases in a mixed manner should then improve compared to the use of nominal parameters, and the TP s across all biases should be close to each other.

In Experiment 1, we investigated continuous crossing with a directional constraint (C/DC) task [5] in which the targets were facing each other (Fig. 1 (i)). In Experiment 2, we looked at continuous crossing within an amplitude constraint (C/AC) task [5] where targets were horizontally aligned (Fig. 1 (ii)). Results showed that in both tasks, applying effective parameters to the Fitts' law model improves the fit when analyzing the data across different biases. Besides, we identified that TP s were smoothed across biases by calculating TP using effective parameters in both tasks. However, we also confirmed that TP was not stable across ID s in the C/DC task, while it was stable in the C/AC task. This indicated that the range of tasks where TP can be used as a measurement of performance in crossing may be limited. We thus also discuss the conditions where TP is stable across ID s in crossing.

2 RELATED WORK

Fitts' law [12, 16] can predict the movement time MT of pointing on the basis of the index of difficulty ID , specifically through the nominal ID (ID_n):

$$MT = a + b \cdot ID_n, \text{ with } ID_n = \log_2(A/W + 1), \quad (1)$$

where A is the amplitude between targets, W is the target width, and a and b are empirical constants.

In the process of deriving the steering law [1], Accot and Zhai showed that the MT of crossing is predicted by Fitts' law. This finding held strongly for various types of crossing tasks [2, 5].

Fitts' law is based on the task parameters W and A , and does not account for the parameters associated with the user's actual behavior. Therefore, replacing A and W with effective parameters enables more accurate prediction of the MT [22]:

$$MT = a + b \cdot ID_e, \text{ with } ID_e = \log_2(A_e/W_e + 1), \quad (2)$$

where A_e is the mean movement distance on the task axis, W_e is $4.133 \cdot \sigma$, and σ is the standard deviation of the cursor endpoints [22]. This definition of W_e ensures that 96% of the endpoints fall inside the target boundary, and A_e is the actual movement distance on average on the task axis; both can more accurately represent the user's behavior [22]. To avoid potential confusion, we denote ID using the nominal parameters as ID_n hereafter, and use ID as a generic term for ID_n and ID_e .

Throughput, TP was standardized by ISO9241-9 and is calculated as follows [23].

$$TP = ID/MT \quad (3)$$

In pointing, TP is considered to be independent of ID [17]. In other words, even if the ID changes, the MT also changes accordingly and thus TP remains (more or less) constant.

Mackenzie and Isokoski conducted a pointing experiment with three $Bias$ conditions: speed-emphasis, accuracy-emphasis, and nominal (i.e., neutral) [18]. In the speed- or accuracy-emphasis condition, the participants were asked to change their MT s by 10% compared with the nominal condition. There was no significant difference in TP using ID_e across different $Bias$ es, and thus TP could smooth out differences in $Bias$. However, Olafsdottir et al. showed

that when the bias is larger than 10%, the invariance of TP was not observed [20].

Zhai et al. revealed that using ID_e showed a higher fit when analyzing the data from multiple biases in a mixed manner (called the *Mixed* analysis condition) than using ID_n in pointing [26]. However, for each individual $Bias$ (such as Accurate, Neutral, and Fast), the ID_n model showed higher fit than the ID_e model. This indicates that the ID_e model improves the fit for *Mixed* at the expense of a higher prediction accuracy of the ID_n model in each individual $Bias$.

Luo and Vogel tested the applicability of W_e to crossing with direct finger input, found that Finger-Fitts law showed a good fit, and compared it with the results using W and W_e [14]. To our knowledge, this is the only study in which W_e was applied to crossing. The purpose of their study was to compare the fits of ID_n , ID_e , and Finger-Fitts ID with a single $Bias$. Still, previous work has not verified whether the effective parameters can smooth the effect of $Bias$ on the fit and TP .

3 EXPERIMENT 1

We conducted a study of the C/DC crossing task where targets face each other (Fig. 1 (i)). Ten university students joined (3 females and 7 males, mean age 20.7, standard deviation 1.06). All participants were right-handed.

3.1 Apparatus

We used a laptop PC (Intel Core i7-11800H, GeForce RTX 3070 Laptop, 16GB RAM, Windows 10 education), LCD tablet (Wacom Cintiq 27QHD, IPS, 569.7×335.6mm, 2560×1440 pixels), and Wacom stylus. The system was made with Unity and displayed in full screen mode.

3.2 Design

For this experiment, we used a $3_{Bias} \times 3_A \times 5_W$ repeated-measures design. The within-subjects factors were $Bias$ (Accurate, Neutral, Fast), amplitude A (46.60 mm, 128.2 mm, 205.0 mm), and width W (1.864 mm, 3.495 mm, 6.524 mm, 11.65 mm, 23.30 mm). A task set comprised the 15 combinations of A and W presented in random order, and 21 such sets were performed in each $Bias$ condition. The ten participants were randomly divided into two groups of five. Group 1 was tested in the order of Neutral, Fast, and Accurate. Group 2 was tested in the order of Neutral, Accurate, and Fast. This ordering, i.e., the Neutral condition as the first condition, allowed the participants to perform the task more rapidly/slowly in the remaining two $Bias$ conditions relative to the first one, which is the same design as used in a previous study [25].

3.3 Procedure

First, the task was explained to the participants, i.e., that they had to perform a stroke from the start target (right) to the end target (left)¹. The task was then completed by passing the start target from right to left and then passing the end target (also from right to left). During the task, participants had to keep the stylus tip on the screen. While the stylus tip was on the screen, a blue trajectory was displayed, and when the stylus tip was lifted off the

¹To prevent the target from being occluded by the hand during the task, we restricted participants to right-handed ones and used right-to-left strokes.

screen, the trajectory disappeared. Before starting each *Bias* condition, participants were instructed to perform the task either “as fast and as accurately as possible” for Neutral, “as fast as possible without worrying about mistakes” for Fast, and “as accurately as possible without worrying about time” for Accurate. Once participants passed through the start target, the task was considered to be started; if participants initially passed outside it, they had to consequently try crossing it again. After the task started, participants were required to cross the end target without lifting the stylus from the screen. If the stylus crossed the end target, we recorded a success; otherwise, an error was recorded. Subsequently, appropriate audio and visual feedback was presented depending if the trial was successful or erroneous. If the stylus was lifted in the middle of a trial, the trial had to be restarted by crossing the start target. After each trial ended, releasing the stylus from the screen displayed a button labeled “Next”, and the participants needed to tap it to proceed to the next trial.

3.4 Measurement

All positions of the stylus tip during task execution were recorded with a time stamp. The dependent variables were *ER* (Error Rate), *MT* (Movement Time), σ (Standard Deviation of Endpoints), and *TP* (Throughput). *ER* was the percentage of trials in which the cursor passed outside the end target. *MT* was the time taken for each trial to complete. For σ , we computed the deviation from the target’s midpoint when the cursor passed through that target (or its vertical extension). W_e was calculated by multiplying σ by 4.133, and 96% of the crossing points at the end targets fell within this W_e [22]. *TP* was calculated by MT/ID , and two types of *TP* were analyzed: TP_n derived by ID_n calculated from *W* and *A*, and TP_e derived by ID_e calculated from W_e and A_e .

4 RESULTS OF EXPERIMENT 1

The first set consisting of 15 trials in each *Bias* condition was considered as practice, and the remaining 9000 trials ($3_{Bias} \times 3_A \times 5_W \times 20_{sets} \times 10_{participants}$) were analyzed. Since ANOVA is robust against normality violation [9, 19], we analyzed all 9000 trials by mean-of-means calculation via RM-ANOVA with a Bonferroni post-hoc test. The independent variables were *Bias*, *A*, and *W*, and the dependent variables *ER* (error rate), *MT*, σ (the deviation from the midpoint of the target at the end of the stroke), and *TP*. Throughout this paper, error bars in the graphs indicate 95% CIs. ***, **, and * in the graphs indicate $p < .001$, $p < .01$, and $p < .05$, respectively.

4.1 Error Rate (ER)

We observed 1187 erroneous trials, where users passed outside the final target (13.2%). Significant main effects were found on *Bias* ($F_{2,18} = 39.0, p < .001, \eta_p^2 = .813$), *A* ($F_{2,18} = 10.1, p < .01, \eta_p^2 = .529$), and *W* ($F_{4,36} = 85.9, p < .001, \eta_p^2 = .905$). Also, we identified significant differences for all *Bias* pairs (Fig. 2 (i)). Further, we found significant interactions on *Bias* \times *A* ($F_{4,36} = 7.27, p < .001, \eta_p^2 = .447$), and *Bias* \times *W* ($F_{8,72} = 23.4, p < .001, \eta_p^2 = .723$).

4.2 Movement Time (MT)

We analyzed the *MT* for all 9000 trials (because W_e normalizes the *ER* to 4%). Significant main effects were found on *Bias* ($F_{2,18} = 43.7, p < .001, \eta_p^2 = .829$), *A* ($F_{2,18} = 110, p < .001, \eta_p^2 = .924$), and *W* ($F_{4,36} = 104, p < .001, \eta_p^2 = .920$). Significant differences were found on all *Bias* pairs (Fig. 2 (ii)). Significant interactions were found on *Bias* \times *A* ($F_{4,36} = 34.3, p < .001, \eta_p^2 = .792$), *Bias* \times *W* ($F_{8,72} = 32.7, p < .001, \eta_p^2 = .784$), *A* \times *W* ($F_{8,72} = 38.9, p < .001, \eta_p^2 = .812$), and *Bias* \times *A* \times *W* ($F_{16,144} = 2.55, p < .01, \eta_p^2 = .221$).

4.3 Standard Deviation at the Endpoint

We analyzed the standard deviation of the endpoint scatter data (σ). Significant main effects were found on *Bias* ($F_{2,18} = 24.7, p < .001, \eta_p^2 = .733$), *A* ($F_{2,18} = 52.2, p < .001, \eta_p^2 = .853$), and *W* ($F_{4,36} = 106, p < .001, \eta_p^2 = .922$). Significant interactions were found on *Bias* \times *A* ($F_{4,36} = 9.67, p < .001, \eta_p^2 = .518$), *Bias* \times *W* ($F_{8,72} = 2.58, p < .05, \eta_p^2 = .223$), and *A* \times *W* ($F_{8,72} = 3.79, p < .001, \eta_p^2 = .296$).

4.4 Model Fitting

For each *Bias*, the baseline Fitts’ law model (ID_n) showed strong fits (Fig. 2 (v)). Using ID_e with W_e^2 showed poorer fits for each *Bias* (Fig. 2 (vi)). Since the number of free parameters is 2 for both ID_n and ID_e , we used non-adjusted R^2 values in this paper. In addition, to analyze the fits in a comparative manner, we used the *AIC* measure [3]. The lower the *AIC*, the better the fit, and a difference of 2 or more is considered to be significant [7]. The differences in the *AIC*s between ID_n and ID_e at each *Bias* were 16 for Neutral, 3 for Fast, and 12 for Accurate, i.e., all larger than 2. Therefore, the ID_n model better predicts the *MT* for each *Bias*.

For a mixed *Bias* (*Mixed*), the fit of the ID_e model was better than the ID_n model (Fig. 2 (v, vi)). The difference in terms of *AIC* was approximately 58 and thus clearly significant. Therefore, the ID_e model is recommended to predict the *MT* from data that may contain multiple biases.

4.5 Throughput (TP)

We analyzed the *TP* calculated using ID_n (TP_n) and ID_e (TP_e).

4.5.1 TP_n . Significant main effects were found on *Bias* ($F_{2,18} = 54.5, p < .001, \eta_p^2 = .858$), *A* ($F_{2,18} = 84.6, p < .001, \eta_p^2 = .904$), and *W* ($F_{4,36} = 16.2, p < .001, \eta_p^2 = .922$). Significant differences were found on all *Bias* pairs (Fig. 2 (iii)). Significant interactions were found on *Bias* \times *A* ($F_{4,36} = 50.8, p < .001, \eta_p^2 = .849$), *Bias* \times *W* ($F_{8,72} = 6.25, p < .001, \eta_p^2 = .410$), *A* \times *W* ($F_{8,72} = 14.3, p < .001, \eta_p^2 = .613$), and *Bias* \times *A* \times *W* ($F_{16,144} = 6.39, p < .001, \eta_p^2 = .415$).

4.5.2 TP_e . Significant main effects were found on *Bias* ($F_{2,18} = 53.0, p < .001, \eta_p^2 = .855$), *A* ($F_{2,18} = 103, p < .001, \eta_p^2 = .919$), and *W* ($F_{4,36} = 69.4, p < .001, \eta_p^2 = .885$). Significant differences were found on all *Bias* pairs (Fig. 2 (iv)). Significant interactions were found on *Bias* \times *A* ($F_{4,36} = 34.8, p < .001, \eta_p^2 = .795$), *Bias* \times *W*

²In Experiment 1, we did not use A_e because the actual cursor trajectory distance along the task axis was always the same as *A*.

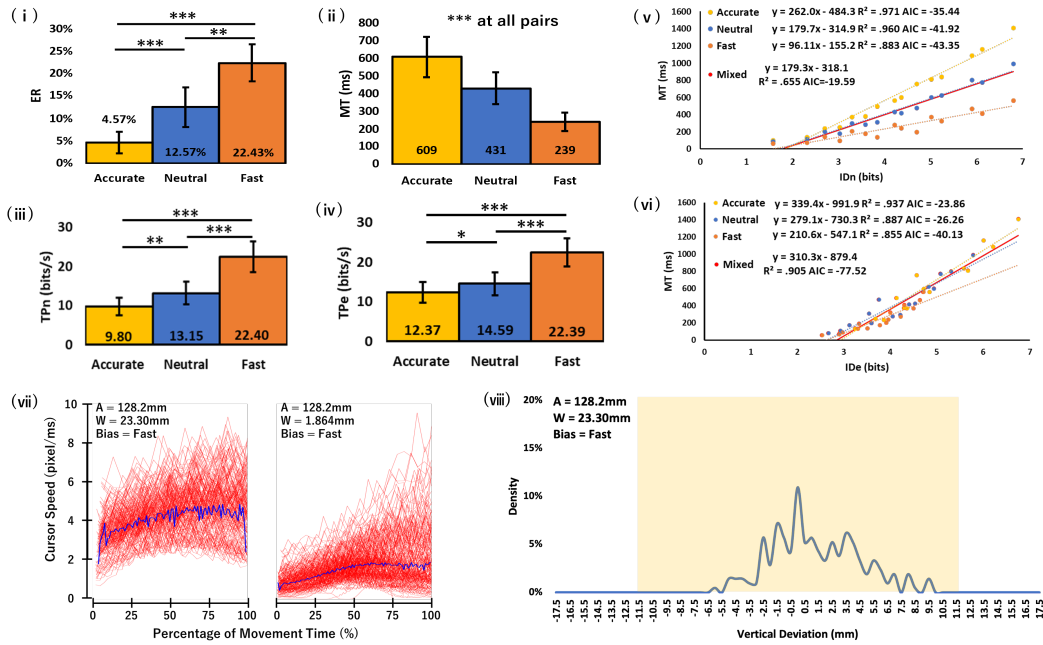

Figure 2: Results of Experiment 1. (i) Error rate across Bias. (ii) Movement time across Bias. (iii) TP_n across Bias. (iv) TP_e across Bias. (v) ID_n vs MT . (vi) ID_e vs MT . (vii) Cursor speed against task progress in %. The blue lines represent the average cursor speed. (viii) Cursor endpoint distribution. Yellow rectangle indicates the task success area.

($F_{8,72} = 2.37, p < .05, \eta_p^2 = .209$), $A \times W$ ($F_{8,72} = 52.4, p < .001, \eta_p^2 = .853$), and $Bias \times A \times W$ ($F_{16,144} = 2.03, p < .05, \eta_p^2 = .184$).

5 DISCUSSION OF EXPERIMENT 1

5.1 Model Fitting

The strong fit of the ID_n model for each $Bias$ indicates that the ID_n model can be used as a model for predicting the MT of the C/DC crossing task (Fig. 2 (v)). This result matches previous studies that investigated only the Neutral condition [2, 5], but extends it for multiple $Bias$ conditions. The ID_n model had strong fits for each $Bias$, and the ID_e model had a strong fit for the *Mixed* bias. This result is similar to a previous study on pointing [26] and demonstrates the ability of the ID_e to normalize the effect of different $Bias$ conditions.

5.2 Throughput

We found that TP was not stable across different ID values for each $Bias$ (Table 1). To analyze this objectively, we computed the standard deviation SD of TP_n across all ID_n values. For Accurate, the mean TP_n was 9.804 bits/s and SD was 4.342 bits/s. Thus, the ratio of SD to the mean TP_n was 44.29%, while this value should be zero if TP_n values for all ID s were the same (as the SD is 0 in this case). Similarly, the values were 36.77% for Neutral, and 34.32% for Fast. For TP_e , we obtained 65.16% for Accurate, 56.83% for Neutral, and 50.80% for Fast (Table 1). In contrast, a previous study on pointing had identified that this metric was 13.2% in the Neutral condition [17]. These results indicate that, in the C/DC task, TP is not a robust metric in terms of the invariance across ID s.

For the invariance across different $Bias$ conditions, TP_e is smoother than TP_n (Fig. 2 (iii, iv)). In TP_n , the difference between Fast and Accurate was 56.27% of the value for Fast, whereas with TP_e , the difference decreased to 44.74%. This value is almost the same as the difference between max-speed and max-accuracy conditions (42%) reported in a previous study on pointing [20]. This confirms the effectiveness of smoothing the effect of $Bias$ conditions through TP_e .

5.3 Cursor Velocity and Endpoint

In low- ID conditions, the cursor velocity was not stable across trials nor participants (Fig. 2 (vii)). Also, there was no clear slowdown of the cursor velocity near the end of task, which is inconsistent with pointing movements [6, 21]. Furthermore, in several condition (16/45), the participant's average MT was smaller than the average human reaction time of 240 ms (Table 1) [8]. These results suggested that participants probably completed the task as a purely ballistic movement under low- ID conditions [13]. Still, the cursor endpoint distribution was concentrated (reasonably well) near the center of the target (Fig. 2 (viii)).

These results point to a potential reason behind the high TP s compared with those for pointing (e.g., the maximum value of TP was 11.54 bits/s for Neutral for a pointing task according to MacKenzie [17]). Our results identify a maximum value of 36.63 bits/s for TP_n for Fast (Table 1). Our high TP s were probably due to the fact that the C/DC task allowed passing near the center of the target with a purely ballistic movement, which made both W_e and MT small and thus TP high.

6 EXPERIMENT 2

To further investigate crossing motions, we conducted a study using the *C/AC* task, where targets are horizontally aligned (Fig. 1 (ii)). The direction of crossing was from bottom to top on the start target (right) and from top to bottom on the end target (left). This task makes it impossible to complete the task by simply moving the stylus in a (more or less) straight line, preventing completion of the task through a simple ballistic movement. The apparatus, design, procedure, and measurements were the same as in Experiment 1. We invited ten new university students (2 females and 8 males, mean age 20.8, standard deviation 1.23). All participants were right-handed. Thus, only the orientation of the target and the participants were changed.

7 RESULTS OF EXPERIMENT 2

The scope of data analyzed, method of analysis, and the independent and dependent variables were all the same as in Experiment 1.

7.1 Error Rate (ER)

We identified 1180 error trials (13.1%). Significant main effects were found on *Bias* ($F_{2,18} = 24.2, p < .001, \eta_p^2 = .729$), *A* ($F_{2,18} = 6.31, p < .01, \eta_p^2 = .412$), and *W* ($F_{4,36} = 38.2, p < .001, \eta_p^2 = .809$). Significant differences were found on all *Bias* pairs (Fig. 3 (i)). Significant interactions were found on *Bias* \times *W* ($F_{8,72} = 14.0, p < .001, \eta_p^2 = .609$).

7.2 Movement Time (MT)

Significant main effects were found on *Bias* ($F_{2,18} = 25.7, p < .001, \eta_p^2 = .740$), *A* ($F_{2,18} = 456, p < .001, \eta_p^2 = .981$), and *W*

($F_{4,36} = 130, p < .001, \eta_p^2 = .935$). Significant differences were found between Neutral and Fast as well as Accurate and Fast (Fig. 3 (ii)). Significant interactions were found on *Bias* \times *A* ($F_{4,36} = 14.9, p < .001, \eta_p^2 = .624$), *Bias* \times *W* ($F_{8,72} = 8.53, p < .001, \eta_p^2 = .487$), *A* \times *W* ($F_{8,72} = 6.51, p < .001, \eta_p^2 = .420$), and *Bias* \times *A* \times *W* ($F_{16,144} = 1.74, p < .05, \eta_p^2 = .162$).

7.3 Standard Deviation of Endpoint

Significant main effects were found on *Bias* ($F_{2,18} = 20.8, p < .001, \eta_p^2 = .698$), and *W* ($F_{4,36} = 149, p < .001, \eta_p^2 = .943$). No significant interactions were found.

7.4 Model Fitting

For each *Bias*, the ID_n model exhibited strong fits (Fig. 3 (v)). The model based on W_e and A_e (the ID_e model)³ showed poorer fits for each *Bias* condition (Fig. 3 (vi)). The differences between the *AIC* of the ID_n model and the ID_e model at each *Bias* were 51 for Neutral, 65 for Fast, and 21 for Accurate, all larger than 2. Therefore, the ID_n model better predicts the *MT* for each *Bias*.

For mixed *Bias* (*Mixed*), the fit of the ID_e model was stronger than the ID_n model (Fig. 3 (v, vi)). The difference of *AIC* was approximately 48, which is clearly a significant difference. Therefore, we recommend the ID_e model to predict the *MT* from data that may contain multiple biases.

³In Experiment 2, we used the ID_e model corrected by W_e and A_e because the actual cursor trajectory distance on the task axis was not always the same as *A*.

7.5 Throughput (TP)

7.5.1 TP_n . Significant main effects were found on $Bias$ ($F_{2,18} = 25.3, p < .001, \eta_p^2 = .738$), and A ($F_{2,18} = 5.40, p < .05, \eta_p^2 = .375$). Significant differences were found between Neutral and Fast as well as Accurate and Fast (Fig. 3 (iii)). Significant interactions were found on $Bias \times A$ ($F_{4,36} = 7.01, p < .001, \eta_p^2 = .438$).

7.5.2 TP_e . Significant main effects were found on $Bias$ ($F_{2,18} = 13.2, p < .001, \eta_p^2 = .594$), and W ($F_{2,18} = 149, p < .001, \eta_p^2 = .808$). Significant differences were found between Neutral and Fast as well as Accurate and Fast (Fig. 3 (iv)). Significant interactions were found on $Bias \times W$ ($F_{8,72} = 8.98, p < .001, \eta_p^2 = .499$), and $A \times W$ ($F_{8,72} = 7.64, p < .001, \eta_p^2 = .459$).

8 DISCUSSION OF EXPERIMENT 2

8.1 Model Fitting

The results were similar to those in Experiment 1. The ID_n model for each $Bias$ showed high fits, indicating the capability of the model to predict the MT well (Fig. 3 (v)). This result supports previous work [2, 5]. The ID_e model had a stronger fit for the *Mixed* bias than using ID_n , again indicating the normalization capability of this measure for mixed $Bias$ data (Fig. 3 (vi)).

8.2 Throughput

In this C/AC task, TP is mostly stable across ID (Table 2). For each $Bias$, we computed the SD of TP_n across all ID_n values. The ratios of SD to the mean were 3.378% for Accurate, 5.354% for Neutral, and 4.955% for Fast. For TP_e , we obtained 11.27% for Accurate, 18.60% for Neutral, and 20.60% for Fast. Compared to the results of Experiment 1, these percentages are more similar to those observed in a previous study on pointing (13.2%) [17]. These indicate less variance of TP across different ID s than for the C/DC task.

TP_e smoothed the TP values across different $Bias$ conditions (Fig. 3 (iii, iv)). For TP_n , the difference between Fast and Accurate was 41.39% of the value of Fast, whereas for TP_e , the difference decreased to 20.69%. This value is smaller than the difference observed in a previous study on pointing (42%) [20]. This confirms the effectiveness of $Bias$ smoothing through the TP_e measure.

8.3 Cursor Velocity and Endpoint

Even in low- ID conditions, the cursor velocity was stable across trials or participants (Fig. 3 (vii)). Also, similar to pointing tasks [6, 21], a slowdown of the cursor velocity near the end of task was observed. Further, the participants' average MT was only in a few conditions (2/45) smaller than the average human reaction time of 240 ms (Table 2) [8]. These results suggest that participants did (in general) not complete the task by performing only a ballistic movement [13]. In addition, cursor endpoints were distributed over a wide range around the task success area (Fig. 3 (viii)). These results (non-ballistic movements and large σ s) are the reasons behind the lower TP_n values (4.99–10.04 bits/s) compared to those in Experiment 1, also resulting in the outcome that TP is more stable across ID s in the C/AC task.

9 GENERAL DISCUSSION AND CONCLUSION

9.1 Effective Parameters

For both the C/DC (Experiment 1) and C/AC tasks (Experiment 2), the ID_e model consistently improved the fit for a *Mixed* bias, whereas the ID_n model consistently demonstrated a better fit for each individual $Bias$ condition. These results indicate that the ID_e term can predict the MT for crossing by smoothing the general effect of the $Bias$ at the expense of strong fit in each individual $Bias$.

9.2 Throughput

We identified that TP for crossing actions is stable across ID s under the following conditions.

- Tasks cannot be completed by ballistic movement even under low- ID conditions.
- The distribution of cursor endpoints is spread widely over the target width.

These conditions are a direct consequence of the outcomes of our two experiments in which only the task geometry was changed. TP was not stable across ID s in the C/DC task (Experiment 1), but was stable in the C/AC task (Experiment 2). In the C/DC task, it was possible to complete the task by a ballistic movement, whereas this was impossible in the C/AC task. In addition, the distribution of cursor endpoints was concentrated near the center of the task in the C/DC task, whereas it was much more widely spread over the target width in the C/AC task.

The effective parameters' smoothing effect on TP_e across $Bias$ es was more clearly identified in Experiment 2. In the C/DC task (Experiment 1), the difference of TP s across $Bias$ was 56.27% for TP_n and 44.74% for TP_e . In the C/AC task (Experiment 2), it was 41.36% for TP_n and 20.72% for TP_e . However, the stability of TP across different ID s at each $Bias$ was consistently higher for TP_n . This indicates that TP_e smoothed the differences between $Bias$ es at the expense of robust stability for each individual $Bias$.

In conclusion, we empirically confirmed the capability of effective parameters to normalize across different $Bias$ conditions. That is, when comparing the performance of multiple input devices or user groups, TP_e smoothes the influence of $Bias$, which is (potentially) different across users (due to their different speed-accuracy tradeoffs), thus enabling a fairer comparison. Therefore, we suggest that in future studies, in addition to reporting MT and ER , TP_e should also be reported. We believe that this will allow researchers to compare performance across studies.

A limitation of this work is that we cannot compare the results from Experiments 1 and 2 in terms of speed-profiles, because the participant groups were different. This also made it difficult to directly compare the smoothing effect on the effective parameters, which was greater in the C/AC task (Experiment 2) than in the C/DC task (Experiment 1). We plan to conduct a within-subjects study to compare these conditions, as well as to test other types of crossing, such as *discrete crossing* where users lift a stylus between two targets off the surface [5], touch-based crossing [14], and crossing in virtual reality [24].
